The treatment of ischemic stroke is often divided between acute interventions (endovascular therapy, intravenous tissue plasminogen activator [IV tPA]) and long-term secondary prevention (modifying risk factors, antithrombotic therapy, etc.). There is great variability between practitioners in the medical management of stroke during hospitalization, in part because of confusing and contradictory results in the literature. Temperature management and therapeutic hypothermia is discussed in this review. In regards to blood pressure targets, while permissive hypertension is often recognized as a beneficial strategy in acute stroke, blood pressure reduction is essential for secondary stroke prevention. We review the literature regarding optimal timing of different blood pressure goals. Finally, the limited literature regarding glycemic control in ischemic stroke patients is discussed.

Currently there is a tremendous amount of research interest in acute reperfusion therapy for patients suffering from acute ischemic stroke. However, other aspects of patient care in acute and subacute stroke are typically considered routine and thus have received less attention. The present guidelines emphasize medical management during the first 24–48 hours after infarction, but do little to address the management in the remainder of hospitalization. In this review article, we will discuss temperature management, blood pressure management, and glycemic control in patients with subacute ischemic stroke. Timely randomized controlled trials (RCTs) have attempted to address these topics, and in this review, we critically examine and summarize the evidence to date. We chose to focus on the management of temperature during the entire inpatient hospital stay. In regards to blood pressure, we focused on the inpatient management without discussing long-term outpatient management, and lastly for glycemic control, we focused on the acute to subacute management.

Temperature management in acute ischemic stroke

The issue of temperature management following acute ischemic stroke is complex and evolving. Hyperthermia is a frequent complication in up to 50% of patients with acute ischemic stroke.1 Recently, the European Stroke Organization (ESO) published evidence-based guidelines in 2015 for the management of temperature in patients with acute ischemic stroke.2 According to these guidelines, in patients with acute ischemic stroke and normothermia, there is no recommended routine prevention of hyperthermia with antipyretics as a means to improve functional outcome and/or survival.2 The quality of evidence is moderate, and the strength of this recommendation is weak.2

Temperature management in acute ischemic stroke

The issue of temperature management following acute ischemic stroke is complex and evolving. Hyperthermia is a frequent complication in up to 50% of patients with acute ischemic stroke.1 Recently, the European Stroke Organization (ESO) published evidence-based guidelines in 2015 for the management of temperature in patients with acute ischemic stroke.2 According to these guidelines, in patients with acute ischemic stroke and normothermia, there is no recommended routine prevention of hyperthermia as a means to improve functional outcome and/or survival.2 The quality of evidence is moderate, and the strength of this recommendation is weak.2

It is possible that therapeutic normothermia or the avoidance of hyperthermia provides the bulk of the benefit seen in prior studies of cardiac arrest survivors.3,4 However, the ESO guidelines state that in patients with acute ischemic stroke and normothermia, there is no recommended routine prevention of hyperthermia with antipyretics as a means to improve functional outcome and/or survival. The quality of evidence is moderate, and the strength of this recommendation is weak.2

Following two previous clinical trials3,4 showing a significant benefit of mild therapeutic hypothermia after out-of-hospital cardiac arrest, one can make a plausible argument that the benefit seen for cardiac arrest patients may also apply to acute ischemic stroke patients. In both scenarios there is ischemia to brain parenchyma secondary to hypoperfusion. However, one must be aware that controversy exists regarding the potential benefit of therapeutic hypothermia for cardiac arrest, especially given the results of the landmark targeted temperature management (TTM) trial.5 In this
large multicenter, international trial including 939 patients there was no benefit conferred to patients treated with hypothermia at a targeted temperature of 33°C compared with a targeted temperature of 36°C.

Keeping this in mind, there are currently several human clinical trials attempting to answer the question of whether therapeutic hypothermia improves clinical outcome in acute ischemic stroke patients. One of these is EuroHYP-16, which is a phase III randomized open label trial to assess the effect of 24 hours of mild hypothermia (target body temperature 34–35°C) on 90 day modified Rankin Scale (mRS) score. The goal of the trial is to enroll 1500 patients. Another important trial is the ICTuS 2/3 study. In this randomized clinical trial, of which 200 patients out of 400 were enrolled, patients had endovascular cooling catheters placed after receiving intravenous thrombolysis with the goal of reaching a target temperature of 33°C within 6 hours of stroke onset, and maintaining that temperature for 24 hours. The trial was stopped early for unclear reasons, and the results are yet to be published. It remains to be seen if this new resurgence in research interest for the use of therapeutic hypothermia for neuroprotection in acute ischemic stroke patients will be fruitful. Presently, the ESO guidelines state that in patients with acute ischemic stroke, induction of hypothermia is not recommended as a means to improve functional outcome and/or survival with a very low quality of evidence and a weak recommendation.

The results of the previously mentioned clinical trials will surely provide us with guidance on therapeutic hypothermia for acute ischemic stroke patients and likely raise more questions as well. Clinical experience has clearly demonstrated that there are patients who have a clinical deterioration with fever and others that do not. Which specific factors determine the response to fever in ischemic stroke patients remains unknown. Perhaps the future will provide us with better knowledge of the specific factors involved which will allow us to provide more tailored therapies for these patients. Until there is convincing evidence for therapeutic hypothermia in ischemic stroke it is advisable to avoid this approach given the inherent risks of hypothermia without any proven benefit at this time. Finally, it appears reasonable to avoid hyperthermia and to aim for a goal of normothermia given that the risks of this approach are minimal and potentially beneficial.

**Blood pressure management**

The management of blood pressure in the setting of acute ischemic infarction is complicated by two opposing concepts: one maintains that acute hypertension has been associated with poor outcomes, the other states that rapid blood pressure reduction may limit the recovery of tissue penumbra. Current American Heart Association/American Stroke Association (AHA/ASA) guidelines recommend treatment of blood pressure above 220 systolic and/or 120 diastolic. However, controversy lies in the management of more modest pressure elevations (i.e. 150–180 systolic), and this is especially true in the timeframe beyond 24–48 hours post-infarction.

The prospective COSSACs trial randomized 763 patients to either resume their outpatient anti-hypertensive regimen or stop for 2 weeks after ischemic or hemorrhagic infarction. At both 2-week and 6-month trial endpoints, there was no significant difference between groups in measures of dependency (characterized by mRS of >3), mortality, or additional cerebrovascular events.

The COSSACs trial lacked sufficient statistical power to detect correlation between blood pressure reduction and improved patient outcomes. However, neutral results were also seen in the larger clinical trial CATIS, which included 4071 ischemic stroke patients. Eligible participants had initial systolic blood pressure between 140 and 220 mm Hg. The treatment group received antihypertensive therapy to reduce systolic blood pressure by 10% to 25% in the first 24 hours after group assignment, followed by a target blood pressure of <140/90, which was achieved at day five. Control subjects received no antihypertensive agents during hospitalization, with an average length of stay of 13 days. Outcome measures were death or major disability (mRS ≥3) at both 14 days (or hospital discharge) and at 3 months. Results indicated no significant differences between groups, with the exception of patients started on antihypertensive therapy greater than 24 hours after symptom onset, who demonstrated improved functional outcome at 3 months. This provides clinical evidence to support the concept of allowing permissive hypertension for the first 24 hours after infarction.

The strengths of CATIS include a large sample population, minimal loss to follow-up, categorization of ischemic stroke etiology, and exclusion of hemorrhagic strokes. Nevertheless, the selection criteria excluded all patients with atrial fibrillation and overrepresented thrombotic stroke. The average National Institutes of Health Stroke Scale (NIHSS) score of participants was only 4 (with an interquartile range of 2–7 in the treatment arm and 3–8 in the control), signifying a selection bias towards less severe strokes, which could account for the apparently blunted effects of aggressive blood pressure management due to a ceiling effect.

The ENOS trial included 4011 patients with greater symptom burden than CATIS, requiring the presence of a motor deficit and averaging an estimated NIHSS score of 11 for each group (Table 1). This was a multi-national, parallel-group trial, in which patients were allocated to receive transdermal glyceryl trinitrate or not, and patients already taking antihypertensives (in either treatment or control) were further randomized to continue or stop their prescribed blood pressure-lowering medications. No difference was found in functional outcome as assessed using ordinal logistic regression of the mRS at 90 days between the treatment and control groups. At 90 days, those allocated to continue anti-hypertensives had higher rates of major disability (Barthel Index <60) (p=0.031) and worse cognitive outcome. One of the possible mechanisms stated by the authors is the higher rate of pneumonia in the group that continued antihypertensive medications, possibly due to aspiration of the medication. In addition, there was significant crossover; only 65% of the patients assigned to continue antihypertensives did in fact continue these medications. The authors conclude that it is reasonable to withhold antihypertensives in the setting of acute stroke until patients are neurologically stable and have appropriate oral/enteral access.

Also examining a timeframe of 1-week post-infarction, the SCAST trial assigned 2029 patients to candesartan or placebo for 7 days following ischemic or hemorrhagic infarct. This demonstrated that the use of candesartan in the days after infarct had little meaningful effect on recurrent stroke, myocardial infarction, vascular death or long-term functional outcome measured at 6 months. These results refute the findings of an earlier smaller industry-sponsored study called ACCESS, which included 342 patients randomized to candesartan therapy or placebo for 7 days post-infarction. Interestingly, there was no significant difference in blood
stroke patients receive intravenous (IV) tPA. Of greater relevance is that taken into context of the fact that only an estimated 5.8% of all ischemic ENOS (10–12% within each of the four groups). This, however, should be demographic in SCAST (8% of experimental and 9% of placebo) and activator (tPA) cases, whereas participants receiving tPA were a minor The COSSACS and CATIS trials excluded all tissue plasminogen activator (tPA) cases, whereas participants receiving tPA were a minor demographic in SCAST (8% of experimental and 9% of placebo) and ENOS (10–12% within each of the four groups). This, however, should be taken into context of the fact that only an estimated 5.8% of all ischemic stroke patients receive intravenous (IV) tPA. Of greater relevance is that randomization to therapy occurred many hours and sometimes days after stroke onset within each of these trials. The benefits of moderate blood pressure control may be more pronounced in the immediate hours after stroke; however, in the CATIS trial there was a statistically significant difference in good outcome when considering patients who were randomized to antihypertensive therapy started greater than 24 hours after acute infarction. Another important consideration that is not accounted for by several of these large clinical trials is the care of the individual patient who displays worsening neurological symptoms with reduction of blood pressure due to a flow limiting stenosis of a large vessel. These patients require close observation with invasive continuous blood pressure monitoring and typically require a higher blood pressure target until the lesion is addressed.

It is worth noting that within each of these trials the mean systolic blood pressure measurements varied minimally between experimental and control arms (Table 1), perhaps limiting measurable effects. COSSACS, CATIS, and SCAST demonstrated effective randomization, but did not analyze outcome measures by stroke subtype (i.e. lacunar, embolic, thrombotic), even though this distinction may be important. When compared to cardioembolic infarcts, lacunar strokes have been shown to present with higher blood pressure on admission as well as higher pressure six days after stroke onset.

mRS = modified Rankin Scale; NIHSS = National Institutes of Health Stroke Scale; OR = odds ratio; pop = population; RR = relative risk; SD = standard deviation; SSS = Scandinavian Stroke Scale; tx = treatment.

It is reasonable to withhold outpatient antihypertensive medications, except beta blockers, which should be decreased by 50% to prevent withdrawal tachycardia, during the acute period after an ischemic stroke.

Acute and Subacute Ischemic Stroke - A Review of Temperature, Blood Pressure and Glycemic Management
**Glycemic control**

Hyperglycemia during acute ischemic infarction may impair recanalization, contribute to cerebral edema, and increase likelihood of hemorrhagic transformation. There is little evidence, however, to guide appropriate targets for blood glucose control in the acute and subacute management of ischemic infarction. The 140–180 mg/dL range proposed by AHA/ASA guidelines is not specific to stroke patients, but instead reinforces findings from the NICE-SUGAR trial (intensive versus conventional glucose control in critically ill patients), which showed that liberalized targets of blood glucose (up to 180 mg/dL) conferred mortality benefits in intensive care unit (ICU) patients. 26–28 On the contrary, a larger study of 180 patients comparing IV infusion of tight glycemic control. Several small studies have correlated acute hyperglycemia with subsequent increase in volume of ischemic infarction.29–31 On the contrary, a larger study of 180 patients comparing IV insulin infusion with subcutaneous therapy demonstrated an increased infarct growth of 17.1 cm³ (p=0.04) for those assigned to intensive IV insulin with a significantly lower average 24-hour blood glucose.32 Future randomized trials should address the specific interplay between different blood glucose targets and the evolution of ischemic infarction, and functional outcomes.

Currently the SHINE trial (Stroke Hyperglycemia Insulin Network Effort) is recruiting a goal of 1400 patients for a randomized, blinded trial of subcutaneous versus IV insulin, with blood glucose targets of 80–130 mg/dL for the infusion group and 80–179 mg/dL for the placebo group. Outcomes will be based on 90-day mRS analyzed in the context of presentation NIHSS score.33 SHINE will no doubt add to the dialogue about glucose management strategies, however, the nuances of insulin protocols (i.e. IV versus subcutaneous insulin) should not overshadow the need for more research on the pathophysiology of hyperglycemia in acute ischemic stroke.

There is a paucity of evidence to guide glycemic control strategies for acute ischemic stroke patients with poorly controlled diabetes, as these patients were not well represented in study populations. For those patients without diabetes or with well-controlled diabetes, the data does not support enough benefit of IV insulin to justify the higher level of nursing care required for continuous insulin protocols in acute ischemic infarction. Though ischemic stroke patients (diabetic and non-diabetic alike) typically present with hyperglycemia, they should be monitored closely to avoid severe hypoglycemic episodes, which carries immediate threats to the brain and even long-term cerebral injury.11 Liberalizing blood glucose goals in order to prevent episodes of severe hypoglycemia is reasonable. More research is clearly needed to provide evidence regarding the optimal blood glucose targets for patients with acute ischemic stroke.

**Conclusions**

In this review article we discussed the management of temperature, blood pressure, and glycemic control in patients with subacute ischemic stroke. The current evidence supporting decision making for these common issues is limited and at times conflicting. Currently it is advisable to not perform therapeutic hypothermia for acute ischemic stroke patients until results from key trials support this practice. The common practice of allowing permissive hypertension for patients with acute ischemic stroke during the subacute period is supported by the literature. Following this time period it is reasonable to aim for normotension. Lastly in terms of glycemic control, extremes at both ends of the spectrum are to be avoided without a clear optimal target range. We have drawn attention to key upcoming clinical trials that may have an impact on the current recommendations for the management of these issues. It is difficult to isolate the treatment effect for each of these interventions and it is likely that these variables are intertwined. A bundled approach that takes into consideration all of these variables needs to be studied. We highlighted the gaps in our current knowledge in the management of these common problems to show areas for future research. Undoubtedly, the results of key trials mentioned in this review will provide us with guidance and further questions.
Acute and Subacute Ischemic Stroke - A Review of Temperature, Blood Pressure and Glycemic Management
